### Introduction (WHY)

To comply with global emission reduction commitments, accurate monitoring and estimation of pollutant emissions are essential. Nitrogen oxides (NO<sub>x</sub>) are gaseous compounds composed mainly of nitrogen and oxygen, predominantly produced during combustion processes. In Spain, key anthropogenic point-source emitters of NO<sub>x</sub> include power plants, cement facilities, petrochemical complexes, steel mills, and refineries. Traditional satellite-based top-down emission estimation techniques rely on computationally demanding inversions using Chemical Transport Models (CTMs) with data assimilation. The capability of satellites to measure atmospheric pollutant concentrations has improved considerably over the years, both in terms of spatial and temporal resolution which has facilitated the implementation of top-down emission estimation techniques. Recent lightweight inversion methods enable daily emissions individual sources estimation satellite using the NO<sub>2</sub> columns from the observations, such as Tropospheric Monitoring Instrument (TROPOMI) onboard the Sentinel-5 Precursor satellite and wind fields from ERA5. This study applies the four lightweight methods—Gaussian Plume (GP), Integrated Mass Enhancement (IME), Cross Sectional Flux (CSF), and Lightweight Cross Sectional Flux (LCSF)—implemented in the Python library ddeq V1.0, to estimate NO<sub>x</sub> emissions from the major point sources across the peninsular and the insular Spain. These estimates incorporate dynamic NO<sub>x</sub> lifetimes derived from CAMS **EAC4** reanalysis data and specific assumptions regarding the NO<sub>x</sub>/NO<sub>2</sub> ratio, effective wind fields, source location, and emission injection characteristics. Emission results from these methods were compared to those obtained with the **HERMES\_**Δ emission model, demonstrating their potential for timely monitoring of pollutant emissions.

### Results: (WHAT)

0.000150

Lifetime sensitivity experiments

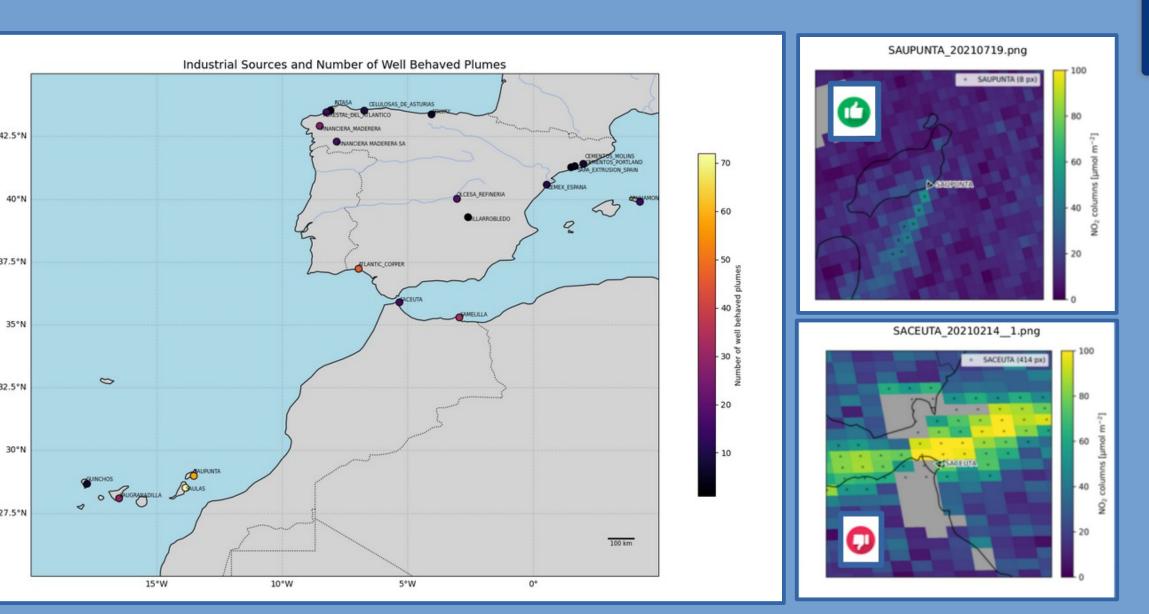

Fig 4: left Number of "good plumes" for 2021 for the Spain insular and peninsular domain and right an example of good and bad plume

WHAT CAN BE CONSIDERED AS A "GOOD PLUME"? Pixel detected can be associated to a point source At least 4 pixels detected

Not pixel detected behind the wind direction

Wind direction of the model at least in the quadrants toward the wind direction Plumes without overlap of concentration from different sources.

No data at all due cloud filtering or interrupted plume

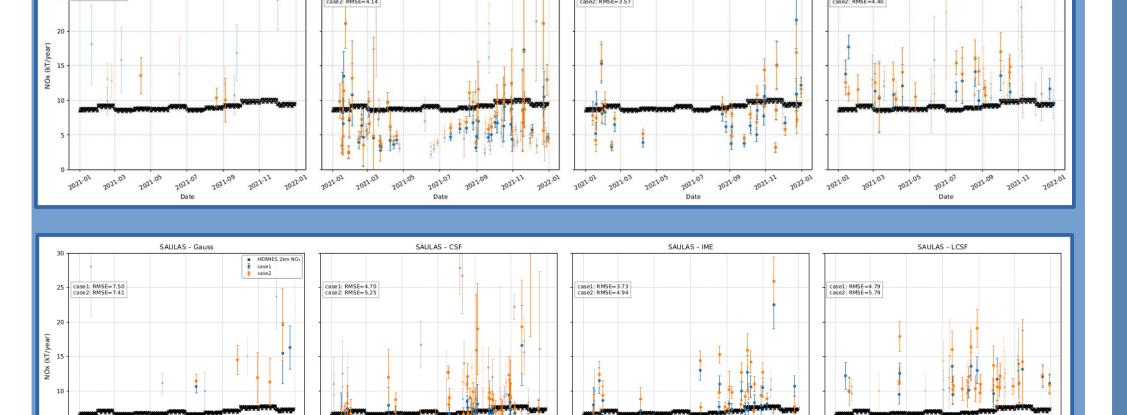

Fig 7: Time series comparison for the Gaussian Plume (GP), Cross Sectional Flux (CSF), Integrated Mass Enhancement (IME) and Lightweight Cross Sectional Flux (LCSF) for two of the top 20 SPAIN high emitter with the HERMES\_Δ. Case 1 corresponds to static

lifetime and Case 2 corresponds to the use of CAMS derived lifetimes

The Spanish NO<sub>2</sub> top emitters are low emission emmiters (<15Kt/y), compared with the high emissor emitters (30Kt/y<) for which the Lightweight methods have been tested before. The results suggest that Lower emissions present problems of plume detectability and quick dilution due to high wind regimes and ozone titration. Discussions (SO WHAT)

## **USA** experiment Lifetime = 2h (RMSE=116.31) Lifetime = 2h (RMSE=12.06) Lifetime = 2h (RMSE=13.57 Fig 8: Comparison of emission estimates from four methods against the reference values for the Intermountain. RMSE is used to evaluate the performance of the methods against the emission reported from the power plant

### Conclusions

• EAC4

Fig 6: Top 20 industrial NO emitters in Spain, shown in red. In blue, the nearest grid points from the CAMS model corresponding to eachsource are marked. Panels (a) to (d) present time series of surface NO2 concentrations to estimated corresponding lifetimes,

go from the expected 10-15 hours in winter to 1-4 hours in summer

NO2 lifetimes calculated using OH and temperature fields, lifetimes values

Lightweight NO<sub>x</sub> emission estimation techniques have proven effective for strong emission sources. Nevertheless, in scenarios characterised by low emissions – for example, the present low-NO<sub>x</sub> context of Spanish power generation – these methods demonstrate diminished accuracy and robustness. the "lighter" the plume, the heavier the challenge for the lightweight satellite methods

It is crucial to enhance the plume detection process, as the presence of points that do not correspond to plumes can compromise the integrity of statistical analysis by introducing erroneous data.

Sources located near the coast are strongly affected by maritime traffic emissions or see breeze wind turbulent patterns. The overlapping transport patterns introduce Significant uncertainty, as individual plumes become difficult to distinguish from background maritime signals. This in general is not a good scenario for the *ddeq* methodology

In the context of the Intermountain scenario, which is regarded as the ideal case, the enhancement of the parametrization of lifetime has been shown to result in an improvement in the performance of all methods.

It is difficult to reach a definitive conclusion regarding the 20 top emitters in Spain; however, there is a tendency for improvement. In such instances, the lightweight methods encounter difficulties in producing estimations, owing to the presence of non-ideal cases, characterised by their non-isolated and non-high emitter status.
